MAXIMUM NEUTRON DENSITY IN A REACTOR WITH LIMITED HEAT-UP
OF THE COOLANT

Y.V.Shevelev

### 1. Introduction

The needs of nuclear material engineering for intensive sources of nuclear radiation are growing all the time. Reactors are being constructed in which the materials and assemblies of various devices can withstand ever increasing fluxes of thermal and fast neutrons, which makes it possible to study destruction of the fuel assemblies (Ref.1), obtain trans-uranium elements (Ref.2), investigate the properties of short-lived nuclei (Ref.3). Ten years ago a thermal neutron flux of about  $10^{14} \text{cm}^{-2} \text{sec}^{-1}$  was considered to be very high whereas at present there are reactors which produce short-time fluxes as high as  $\sim 10^{16} \text{cm}^{-2} \text{sec}^{-1}$ . It may be supposed that the fluxes will grow to still higher values.

However, since each specific method of obtaining intensive nuclear radiations has its limitations these methods will change in quality. One of the new methods is the use of underground nuclear explosions for obtaining powerful neutron impulses (Ref.4).

Studying the maximum petentialities of the used pewerful neutron sources is a main theoretical problem. It will be shown below that for a given amount of energy which can be taken by one volume unit of the coolant there is a constant limit to which the neutron density in the core of the reactor can be increased, regardless of the known reactor type.

The paper decels with pulsed reactors, reactors with fuel metion relative to the core, reactors with transfer of heat from fuel to coolant and reactors with opposing coolant streams.

25 YEAR RE-REVIEW

# 2. Pulsed reactors

The pulsed reactor keeps operating unit it heats up to the limit imposed by its construction and the materials. Then the reactor has to cool down before it again becomes operative (the heat loss during the operation is usually negligibly small).

Apart from cooling the operation cycle of a pulsed reactor can be divided into three stages: build-up of power to the maximum level operation at this level, collapse of the power. As the reactor heats up during all three stages, the shorter the duration of each stage, the higher the maximum power.

The rate of neutron density n growth (and, consequently, the rate of power growth) is limited by an exponential curve with a period.

$$T_{min} = \frac{1}{V\Sigma(K_{\phi}^{-1})} \tag{1}$$

where  $(K_{\infty}-1)$  is the maximum possible supercriticality of the reactor (of infinite dimensions), V - velocity of fission-producing neutrons,  $\Sigma$  -absorbtion cross-section of these neutrons. With such neutron density growth when it reaches maximum the integral (in time) neutron density is equal to

$$\int ndt = T_{min} max$$
 (2)

Accordingly, the heat accumulated per volume unit of the reactor will be equal to  $Q = T_{\min} n_{\max} \bigvee \bigcup_{i \in \mathcal{I}_{i}} \sum_{i \in \mathcal{I}_{i}} n_{\max} \sum_{i \in \mathcal{I}_{i}} n_{\max} \sum_{i \in \mathcal{I}_{i}} n_{\max} \sum_{i \in \mathcal{I}_{i}} n_{\min} n_{\min}$ 

The value of C cannot exceed the permissible heat liberation per volume unit of the reactor Q The equality of Q and Q is possible only with the zero duration of the operating duty and instanteneous collapse of power. Therefore the neutron density cannot exceed the value given by

$$\Pi_{max} = \frac{Q_{max} Y_{f}}{T_{min} V \{ K_{co} E_{f}} \tag{3}$$

which means that in accordance with (1)

$$\Pi_{max} = \left( \frac{\gamma_p}{F} - \frac{\gamma_p}{K_{co}} \right) \frac{Q_{max}}{E_f}$$

$$- 2 - (4)$$

(ii)

Let us represent  $Q_{max}$  as the number of atoms per volume unit of the reactor (N) multiplied by the maximum energy which can be on the average imparted to each atom ( $\mathcal{E}$ ):

$$Q_{max}: NE$$
 (5)

Then

$$n_{max} = \left( \frac{y_{\ell}}{\kappa_{\infty}} - \frac{y_{\ell}}{\kappa_{\infty}} \right) \frac{\xi}{\xi_{\ell}} N$$
 (6)

If the construction of the reactor does not provide for the transition of the core to the plasma state, the value of E must not exceed several tenths of an electron-volt. Assuming that

we obtain

$$n_{\rm max} \sim 10^{14} {\rm cm}^{-3}$$

The neutron flux depends on the energy of the neutrons which cause the bulk of fissions. In the thermal energy region the cross-section of many important reactions with neutrons follows approximately the 1/V law, therefore "n" is in many cases a sufficient characteristic for thermal-neutron reactors. It is possible, by way of illustration, to calculate the flux referred to a room temperature, regardless of actual average temperature, i.e. to multiply "n" by 2...10 cm/sec. The result is

$$\phi_{\rm max} \sim 2.10^{19} {\rm cm}^{-2} {\rm sec}^{-1}$$

In practice it is rather difficult to shut down instantaneously a pulsed reactor with large super criticality i.e. for the time smaller than  $T_{\min}$ . If the reactor is shut down due to the negative linear thermal effect the reactivity decrease is proportional to the accumulated heat;  $n_{\max}$  drops four times. Besides, the real supercriticality is always smaller than  $K_{\infty}$  -1.

he neutron density can be increased beyond  $10^{14}$ cm<sup>-3</sup> only in plasma-type reactors, i.e. by heating the core to  $10^4$  deg. and above. However, the reactors of such types differ in principle from those which have so far been mastered by the reactor engineering.

It may be mentioned that  $\mathcal{E}$  /E<sub>f</sub> is the ratio of the fissioned

nuclei to the full number of the nuclei in the core ( $Q_{max}/E_f$  is the number of fission events per volume unit). Consequently  $\mathcal{E}/E_f < 1$ . The ultimate limit, which is not achieved even in the atom bomb

$$n_{\text{max}} = (Y_{\text{f}} - 1) \text{ N} \sim 10^{23} \text{cm}^{-3}$$

### 3. Reacters with Fuel Metion Relative to the Core

In these reactors the fuel, theroughly mixed with liquid or gaseous coolant, moves through the core at a high speed (homogeneous reactors). These reactors also include cyclopiles (Ref.5) in which the zone with a high neutron flux moves along the long reactor body. Since it does not matter what is at rest — the geometrical region where fission is going on (core) or the mixture of the fuel with the coolant, this type of reactor actually differs only in the fact that the coolant may be in any aggregation state and, particularly, in a solid state.

Let us assume that a wave of the neutron flux and of the heating-up travels along the reactor with a velocity U. The absorbers which were used to make the reactor subcritical are removed from the cold reactor body at the forward front of the wave. Absorbers may be inserted into the hot core at the rear front of the wave to shut down the chain reaction so as to avoid excessive heating. If the negative thermal effect is sufficiently large there is no need to use rear absorbers.

The homogeneous reactors are not usually provided with front or rear absorbers. Instead, the cross-section of the stream sharply narrowed, as it leaves the core, the neutron leakage increases and the reaction is shut down over a short section.

For the rough description of the process given below the difference between the insertion of an absorber and narrowing of the cross-section is inessential.

It would seem at a first glance that in this type of reactor the neutron density can be increased limitless even with a given heating limit by merely increasing the velocity U of the motion of the boundary which divides the region of the cold subcritical reactor from the supercritical region of the core. of course, this involves engineering problems - the tested materials should steadily keep up with the travelling neutron field, so that they were subjected to irradiation during the time while the wave travels round the reactor body (if the core is stationary the mixture of the fuel and coolant must be circulated at a high velocity). Besides to preserve the duration of irradiation at the higher velocities the reactor length must be increased respectively (if the reactor is to cool down while the wave travells round the reactor the capacity of the cooling system must grow with the velocity U). However, these problems can be solved in principle.

It appars, however, that as the velocity U increases the neutron density first grows in proportion to U but then tends to a certain limit. To illustrate this let us compose a simplified unidimensional single-group equation which describes the distribution of the neutron flux  $\phi$  along the core:

$$\Re\left(\frac{\partial^2 \phi}{\partial x^2} + \chi^2 \phi\right) = \frac{\partial n}{\partial t} = 1 + \frac{\partial \phi}{\partial t} \tag{7}$$

Here  $\chi_{\chi}^2$  - the difference between the material parameter and the radial geometric parameter V and D - the velosity and diffusion constant for the fission-producing neutrons.

In the case of a travelling wave the time derivative (  $\phi$  is the function x - ut) can be expressed through the coordinate derivative

$$\frac{\partial \phi}{\partial t} = -\mathcal{U} \frac{\partial \phi}{\partial x} \tag{8}$$

We obtain the equation

$$\frac{d^2\phi}{dx^2} + \frac{u}{vp} \frac{d\phi}{dx} + \partial c_x^2 \phi = 0 \tag{9}$$

Outside the core  $\mathcal{X}_{x}^{2}$  is a high negative value. Inside the core  $\mathcal{X}_{x}^{2}$  and VD are, generally speaking, variables as the heating affects the neutron balance and the operating spectrum. This fact is very important when  $n_{max}$  has to be calculated for some specific reactor. To find the maximum value  $n_{max}$  they can be substituted with some average values.

Let us first assume that in the reacter pertiens blackened by the absorbers the flux is zero, i.e.  $\mathcal{X}_{X}^{2}=-\infty$ . Then the

critical length of the core (the distance between the front and rear absorbers) is equal to

$$\mathcal{X}_{x} = \mathcal{T}_{x} \times \mathcal{X}_{1} - \mathcal{Y}_{2} \tag{10}$$

where

At  $\gamma$ =1, obtain  $a_x$ =  $\infty$  . The corresponding velocity U is yet small as compared with the neutron velocity as D  $\mathcal{E}_x$  << 1. At  $\gamma$  1 Eq.(9) (9) has no solution that would become zero at two values of X. This case will be discussed separately.

The distribution of the flux and the neutron density within the reactor is described by the formula

 $n \sim \phi \sim e^{-x \frac{\partial^2 x}{\partial s} i n} \left( x \frac{\partial^2 x}{\partial s} \sqrt{1 - y^2} \right)$  (12)

(X = 0 - rear boundary, X = a<sub>x</sub> - front boundary of the reaction zone.)

At small values of \( \gamma\) the curve is symmetrical, but when \( \gamma\)
is close to 1 the maximum is displaced towards the rear front of
the wave. The non-uniformity factor of the neutron flux distribution
within the core is equal to

$$K_{x} = \frac{n_{max}}{n_{ev}} = \frac{f_{1}}{\sqrt{1-y^{2}}} \frac{\ell - \frac{y}{\sqrt{1-y^{2}}} \operatorname{arcdg} \frac{\sqrt{1-y^{2}}}{y}}{1 + \ell - \frac{y}{\sqrt{1-y^{2}}} f_{1}}$$

$$\tag{13}$$

The integral neutron density  $\int_{n}^{\infty} dt$  for some point of the reactor can be represented in the form

where  $a_x/u$  - the time taken by the neutron wave to pass the point. Substituting  $n_{av}$  with  $n_{max}$  we obtain

$$\int ndt = n_{max} T_{eff}$$
 (14)

where

$$T_{\text{eff}} = \frac{a_{x}}{u k_{x}} \tag{15}$$

The fermula (14) is similar to (2). Therefore, the equation for  $n_{max}$  can be obtained by substituting  $T_{min}$  in Eq.(3) with  $T_{eff.}$  - the effective width of the curve n (t):

(16)

Substituting  $T_{\rm eff}$  in Eq.(16) with the corresponding expression given by Eq.(15), substituting U in accordance with Eq.(11) and using Eq.(10) and (13) we obtain

$$\Pi_{max} = \left(V_f - \frac{V_f}{K_{\infty}}\right) \frac{Q_{max}}{E_f} \Psi(\gamma) \frac{\chi_x^2 \mathcal{D}}{\sum (K_{\infty} - 1)} \tag{17}$$

where

$$\Psi(8) = 8 \frac{2}{1 + \ell - \frac{8}{\sqrt{1 - 8^2}} \pi} \exp\left(-\frac{8}{\sqrt{1 - 8^2}} \operatorname{nicky} \frac{\sqrt{1 - 8^2}}{8}\right)$$
 (18)

Function  $\gamma$  monotonically increases with  $\gamma$  to equal  $\frac{2}{\kappa}$  at  $\gamma$  =1. Factor  $\frac{\mathcal{L}_{\kappa}^{2}\mathcal{D}}{\Sigma(\kappa_{\kappa}^{-1})}$  is below unity and becomes unity only if  $\mathcal{L}_{\kappa}^{2}$  coincides with the material parameter (very great transverse dimensions) and the migration area is fully described by  $\mathbb{D}/\Sigma$ .

Let us now take up the case when  $\gamma > 1$ . We will write the solution in the form

$$n \sim \ell^{-x} x_x^{\delta} sh \left[ (x+\delta) x_x \sqrt{\delta^2 - 1} \right]$$
 (19)

It does not become zero at X=0 or X=a\_x. However, if  $\delta$  is sufficiently small and a\_x sufficiently great, n will be small at both boundaries of the core. This is in accordance with the actual condition that in the blackened areas n  $\neq$  0. The neutron density here depends on power of the available neutron sources (spontaneous fission, external irradiation, at the rear front-delayed neutrons) and on the degree of subcriticality. Naturally, it is very small compared with n<sub>max</sub>, especially at the forward front. Asymptotically Function (19) has an exponential form

$$\exp\left[-x\,\varkappa_{\chi}\left(\gamma-\sqrt{\gamma^{2}-1}\right)\right]$$

Therefore, if at  $X = a_x$  the flux is to be by several orders smaller than  $\phi_{\max}$  the value  $\mathcal{A}_x \mathcal{X}_x \left( \sqrt{1 - \sqrt{1 - 1}} \right)$  should be equal to at least a two-digit number.

The non-uniformity factor is now described by the formula

(20)

For n we obtain the same formula (17) in which, however

$$\Upsilon(x) = 2\gamma \exp\left(-\frac{x}{2\sqrt{x^2-1}} \ln \frac{x+\sqrt{x^2-1}}{x-\sqrt{x^2-1}}\right), \quad \chi \leq 1$$
 (21)

At  $\gamma$  =1,  $\gamma$  remains equal to  $\frac{2}{7}$  . As  $\gamma$  rises the function  $\gamma$  omnotonically increases tending to unity at  $\gamma$ 

Therefore, the maximum neutron density  $(U \rightarrow \omega, \frac{\chi_1^2 \Omega}{\Sigma} + \kappa_{\omega^{-1}})$  does not differ from the maximum neutron density for pulsed reactors. Of course, instantaneous shut down of the reaction by the rear absorbers  $(\delta = 0)$  is an idealization, as is the instantaneous shut down of a pulsed reactor.

As is the case with pulsed reactor  $n_{max}$  decreases if negative thermal effect (decrease of  $\mathcal{H}_{x}^{2}$  during heat-up) is used instead of forced shut down.

# 4. Reactors with Heat Transfer from Fuel to Coolant

In reactors of such type high neutron density can be obtained only with small transverse dimensions of the fuel elements, minimum volume of the structural elements and small transverse dimensions of channels with the coolant. Therefore, physically this reactor is almost homogeneous type. Let us represent this reactor schematically in the form of a mixture of nuclei of two kinds. Fuel nuclei with atomic weight  $\mathbf{A}_1$  are as a rule at rest. The macroscopic scattering cross-section in the fuel elements is equal to  $\mathbf{\Sigma}_{\mathcal{A}}$  and their volume part in the reactor is  $\mathbf{S}_1$ . The average cosine of the scattering angle in the centre-of-mass system is  $\mathcal{M}_1$ . For the coelant whose nuclei move at an average velocity of  $\mathbf{U}_2$  the corresponding characteristics are designated by index 2. Then the values

$$P_{i} = \frac{S_{i} \Sigma_{S_{i}}}{S_{i} \Sigma_{S_{i}} + S_{L} \Sigma_{S_{L}}}, \quad P_{L} = 1 - P_{i} = \frac{S_{L} \Sigma_{S_{L}}}{S_{i} \Sigma_{S_{L}} + S_{L} \Sigma_{S_{L}}}$$
(22)

will be the probabilities of scattering on the fuel and coolant nuclei.

The velocity  $V_o$  of a newly formed neutron may be directed to any side with equal probability. Therefore the average value of the vector  $V_o$  is equal to zero. Assuming that  $P_i$ ,  $\mathcal{M}_i$  are independent from the neutron energy it is quite easy to calculate the average value of the vector  $v_k$  - the velocity of the neutron after

K collision events (See the Appendix):

$$\overline{V}_{K} = \frac{1 - \left[ \frac{P_{1}(1+p_{1},H_{1})}{1+H_{1}} + \frac{P_{2}(1+p_{1},H_{2})}{1+H_{2}} \right] - \frac{(1-M_{2})A_{2}}{1+A_{2}} - P_{2} Tb_{2}}{1+A_{2}} = \frac{1 - \left[ \frac{P_{1}(1+p_{1},H_{2})}{1+H_{1}} + \frac{P_{2}(1+p_{1},H_{2})}{1+A_{2}} \right]}{1+A_{2}} - P_{2} Tb_{2} \quad (23)$$

The time taken by the several initial collisions of the neutron is usually short as compared to the neutron life. Therefore, practically during its entire life the neutron in general moves in the direction of the coolant flow (i.e. in the negative direction) at a velocity the absolute value of which es equal to

$$7 l_{av} = \frac{1 - \frac{1 + \rho_{12} A_{2}}{1 + \rho_{1}}}{1 - \frac{P_{1} (1 + \rho_{1}) A_{2}}{1 + \rho_{1}} - \frac{P_{2} (1 + \rho_{1})}{1 + \rho_{2}}} P_{3} ll_{2}$$
(24)

As U<sub>2</sub> is small as compared to V, the variation of the absolute velocity of a neutron with time practically is similar to that with slowing down in a stationary medium. Consequently motion of a part of the medium can be well evaluated by evaluating the averaged motion of the neutrons at a velocity U<sub>av</sub>. An additional term will appear in the balance equation of a stationary reactor, which will be written in the right-hand part:

$$\mathcal{J}\left(\frac{d^2\phi}{dx^2} + \mathcal{X}_x^2\phi\right) = -\mathcal{U}_{av} \cdot \frac{dn}{dx} = -\frac{\mathcal{U}_{av}}{\mathcal{V}} \cdot \frac{d\phi}{dx}$$
 (25)

(a similar equation is treated in Ref.6).

Equation (25) is obtained from (9) by substituting U with  $U_{av}$ . Therefore it is desirable to redetermine the parameter  $\chi$ :

$$\gamma = \frac{\mathcal{U}ax}{2\sqrt{2}\chi^2} \tag{26}$$

However, the fermula (15) for  $T_{\rm eff}$  still contains  $U_2$ . As a result an additional factor-ratio  $U_2/U_{\rm av}$  appears in the formula (17). Simultaneously,  $Q_{\rm max}$  has to be substituted with  $S_2Q_{\rm max}$ , i.e. heat accumulated by the coolant has to be distributed throughout the entire core. We obtain

$$\mathcal{U}_{max} = \left( \mathbf{y}_{p} - \frac{V_{p}}{K_{\infty}} \right) = \frac{Q_{max}}{P_{1}} \cdot \mathbf{y} \cdot \left( \mathbf{y} \right) = \frac{\mathcal{X}_{x}^{2} \cdot \mathfrak{D}}{\sum \left( K_{\infty}^{-1} \right)} = \frac{S_{2} \cdot \mathcal{U}_{2}}{I \cdot l \cdot a_{2}}. \tag{27}$$

( $\Sigma$  - the absorbtion cross-section in the core and not in the coolant). To enable the reaction to be maintained at  $\gamma>1$  the coolant entering the reactor must carry at least—small quantities of neutrons. Otherwise, even with  $\gamma$  -1 the reaction can not be maintained in the reactor with a finite height, of the core.

To sum up, the maximum neutron density in the reactor with stationary fuel and moving coelant differs from the maximum density in the homogeneous or pulsed reactor by an additional factor  $S_2U_2/U_{av}$ . In accordance with (22) and (24) this factor is equal to

$$\frac{S_2 U_2}{U \text{ av}} = \left[1 + S, \left(\frac{\sum_{s_2} - 1}{\sum_{s_2} - 1}\right)\right] \frac{1 - \frac{P_1(1 + M_1, H_2)}{1 + H_1} - \frac{P_2(1 + M_2, H_2)}{1 + H_2}}{1 - \frac{1 + M_2 H_2}{1 + H_2}}$$
(28)

If  $S_{7}O$  the factor is equal to unity, as would be expected (homogeneous reactor). It is also equal to unity when  $A_1$ ,  $M_1$ ,  $\sum_{S_1}$  are equal to  $A_2$ ,  $M_2$ ,  $\sum_{S_2}$ , respectively. In the general case it may differ somewhat from unity, but it is very doubtful that any substantial gain can be obtained from the stationary condition of the fuel (it is not worthwhile to increase  $\frac{\sum_{S_1}}{\sum_{S_2}}$  at the expense of low density of the coolant since  $Q_{\text{max}}$  also decreases).

# 5. Reactors with Opposing Streams

The slower rate of growth of n when the coolant velocity approaches  $2VD\mathscr{X}_{\chi}$  is due to the increase in the length of the region where the chain reacton is going on since with  $(U+\infty)$  the length of the fission reaction zone rises in proportion to U the heat liberation per volume unit of the core no longer grows, i.e. the neutron density n reaches its maximum limit determined by the formula (4). To evercome this limit the amount of neutrons carried away from the reactor by the coolant must be decreased. As was kindly advised to the author by N.N.Ponomarev-Stepney this can be achieved by splitting the coolant flow into streams and directing the adjacent streams so that they face each other. Let us find the required degree of the coolant flow splitting. The reactor to be assumed homogeneous. The streams will have rectangular section with sides  $q_y$  and  $q_z$  times

smaller than the corresponding dimensions of the reactor ay and  $a_z$ . If the velocities of the streams  $\pm U_{\bullet}$ , then, using the Fourier series for a "chessboard" we obtain:

$$U\left(y,\chi\right) = U_0 \sum_{s=0}^{\infty} \sum_{t=0}^{\infty} \frac{(4f_T)^2}{(2sn)(2t+1)} \sin\left[\left(2s+1\right)q_y \frac{J_1}{a_y}y\right] \sin\left[\left(2tn\right)q_y \frac{J_2}{a_z}\chi\right]$$
(29)

This formula must be substituted into the equation

$$\nabla \dot{\phi} + \mathcal{X}^2 \phi + \frac{\mathcal{U}}{\nabla \mathcal{D}} \frac{\partial \phi}{\partial x} = 0 \tag{30}$$

which is true if  $a_y/q_y$  and  $a_z/q_z$  are great as compared to D. Let us seek the solution of (30) in the form of a series by the inherent functions of "an unperturbed" operator

$$H_0 = \nabla^2 + \chi^2$$
 (31)

having the form

$$Y_{n,\ell,\kappa}(x,y,z) = Sin(n\frac{\pi}{a_x}x)Sin(\ell\frac{\pi}{a_y}y)Sin(\kappa\frac{\pi}{a_z}z)$$
(32)

The corresponding inherent values are equal to

$$\lambda_{n,\ell,K} = \int \mathcal{X}^{2} - (h^{2} - 1) \frac{\pi^{2}}{\alpha_{x}^{2}} - (\ell^{2} - 1) \frac{\pi^{2}}{\alpha_{y}^{2}} - (K^{2} - 1) \frac{\pi^{2}}{\alpha_{x}^{2}}$$
(33)

where

$$Sx^{2} = x^{2} - \left(\frac{\pi^{2}}{a_{x}^{2}} + \frac{\pi^{2}}{a_{y}^{2}} + \frac{\pi^{2}}{a_{z}^{2}}\right)$$
(34)

is the variation of the critical material parameter caused by "perturbation" - motion of the coolant (the perturbation operator is equal to  $SH=\frac{u}{\sqrt{2}}\cdot\frac{\partial}{\partial x}$ ).

For expansion factors  $\phi$  by  $\gamma_{n,l,k}$  we obtain, in the

usual way a set of equations in the form:

The matrix element contained in this equation is determined by the relation

$$SH_{n,\ell,K}$$
; m. R.  $u = \int Y_{n,\ell,K} \frac{u}{vo} \frac{\partial}{\partial x} Y_{m,e,u} \frac{\partial}{\partial x} dx dy dz / SY_{n,\ell,K}^2 dx dy dz$  and is equal to

$$\frac{mn}{n^{2}-m^{2}} \frac{\ell PKU q_{y} q_{z}}{[(2s+1)^{2}q_{y}^{2}-(\ell-P)^{2}][(2s+1)^{2}q_{z}^{2}-(k-\mu)^{2}][(2t+1)^{2}q_{z}^{2}-(k-\mu)^{2}]}$$
where

where

The equations become simpler at great  $q_y, q_z$ , when approximately

$$C_{n,l,k} = \frac{\frac{\pi}{\alpha_{k}} \frac{\mathcal{U}_{o}}{\mathcal{V}^{2}}}{(n^{l}+)\frac{\pi^{2}}{a_{k}^{2}} + (l^{2}-l)\frac{\pi^{2}}{a_{k}^{2}} + (K^{2}-l)\frac{\pi^{2}}{a_{k}^{2}} - S_{2} = \sum_{m,n,u} \sum_{s=0}^{\infty} \sum_{l=0}^{\infty} \left(\frac{1}{2}\right)^{3} \Delta(m \circ n) \frac{mn}{n^{l}-m^{2}} (38)$$

• 
$$\Delta \left(P + \{+q_y\}\right) \Delta \left(K + U + q_z\right) \frac{C_{m,p,u}}{8^2 (2S + 1)(2t + 1)}$$
• 
$$\left[\frac{1}{(2S + 1) q_y - (p + \ell)} \frac{1}{(2S + 1) q_y - (p + \ell)}\right] \left[\frac{1}{(2\ell + 1) q_z - (K + U)} - \frac{1}{(2\ell + 1) q_z - (K + U)}\right]$$
It can be easily seen that is

It can be easily seen that if values  $n_1 / (2s+1)q_y-1/$ , (2t+1)are of the order of the unity, then

$$C_{n,\ell,k} \sim \frac{C_{l,l,l}}{(2s+1)(2t+1)} \qquad \frac{\pi}{(2s+1)^2 q^{\frac{1}{2}} \frac{\pi^{\frac{1}{2}}}{a^{\frac{1}{2}}} + (2t+1)^2 q^{\frac{1}{2} \frac{\pi^{\frac{1}{2}}}{a^{\frac{1}{2}}}}}$$

If n, l, k are of the order of the unity, then

$$C_{n,\ell,z} \sim C_{1,1,1} \qquad \frac{\frac{T}{a_x} \quad u_c}{\frac{2}{y^2} \frac{\pi^2}{a_y^2} + q_z^2 \frac{T^2}{a_z^2}}$$

If n=1=k=1, only those terms are essential in the right-hand part of (38) in which m  $/(2s+1)q_y-P$  /,  $/(2t+1)q_z-U$  / is of the order of the unity.

Bearing in mind these considerations the following formula can be easily obtained to change  $\mathcal{X}^{\perp}$  compensating for the entranment and carry-ever of the neutrons by the flow:

$$\frac{g x^{2}}{(\pi/a_{x})^{2}} = \frac{g'st_{x}}{16} \left[ \sum_{s=0}^{\infty} \sum_{t=0}^{\infty} \frac{q_{s}^{2} \frac{\pi^{2}}{a_{s}^{2}} + q_{x}^{2} \frac{\pi^{2}}{a_{x}^{2}}}{(2s+1)^{2}q_{s}^{2} \frac{\pi^{2}}{a_{s}^{2}} + (2t+1)^{2}q_{x}^{2} \frac{\pi^{2}}{a_{x}^{2}}} \frac{1}{(2s+1)^{2}(2t+1)^{2}} \right]$$
(39)

where

$$\mathcal{F} \quad \text{str} = \frac{\mathcal{U}_o}{2 \sqrt{2} \mathcal{X} s t_z} \tag{40}$$

and

$$\mathbf{z}_{\text{str}}^{2} = q_{y}^{2} \frac{\pi^{2}}{\alpha_{y}^{2}} + q_{z}^{2} \frac{\pi^{2}}{\alpha_{z}^{2}}$$
(41)

is the geometric parameter of one stream.

The factor in square brackets in (39) does not practically differ from unity so that the effect of the neutron entrainment on the critical size is insignificant if  $\gamma_{\rm str} < 1$ .

Disregarding the factor which is close to unity and considering (34) we write (39) as follows:

$$\frac{\left(\mathcal{F} h_{x}\right)^{2}}{\mathcal{X}^{2}} = \frac{1 - \left(\frac{2}{2} / \mathcal{X}^{2}\right)}{1 + \left(\frac{6}{2} / 4q\right)^{2}},$$
(42)

where

$$\mathcal{X}_{\mathbf{z}'}^{2} = \frac{\mathcal{I}^{2}}{\alpha_{\mathbf{y}}^{2}} + \frac{\mathcal{I}^{2}}{\alpha_{\mathbf{z}}^{2}} \tag{43}$$

$$\gamma_o = \frac{u_o}{2v_{\mathcal{D}} \mathcal{Z}} \tag{44}$$

$$q^{2} = \frac{q^{2} \frac{\pi^{2}}{a_{y}^{2}} + q_{z}^{2} \frac{\pi^{2}}{a_{z}^{2}}}{\frac{\pi^{2}}{a_{y}^{2}} + \frac{\pi^{2}}{a_{z}^{2}}} = \frac{\mathcal{Z}^{2}_{SFE}}{\mathcal{Z}^{2}_{E}}$$

$$(45)$$

The value q characterizes the degree of splitting the flow into streams. For each value of the parameter (  $\chi_{-/4q}$ ) there is

an optimum value of  $\mathcal{X}_{\mathcal{P}}^{2}/\mathcal{Z}^{2}$  at which  $a_{\mathbf{x}}$  is closest to the minimum value of  $\mathcal{F}/\mathbf{x}$ , i.e. the neutron density is maximum. To ensure that the difference between  $a_{\mathbf{x}}$  and  $\mathcal{F}/\mathcal{X}$  is not great the parameter (  $\partial \circ /4\mathbf{q}$ ) must not exceed unity. Whence the required degree of splitting  $\mathbf{x}$ :

$$q \sim \gamma_{n}/4$$
 (46)

For example, to raise the neutron density by one order higher as to its maximum value in a pulsed reactor to must be approximately 15, Q q, approximately 4.

# 6. Conclusion

It is not an easy problem to obtain neutron densities olose to the maximum values determined by the formulas (4) and (27). With fast-neutron reactors this becomes downright impossible since there are no methods by which the reaction can be shut down during the time  $T_{\min}$  determined by the formula (1). Even scattering of the materials due to their thermal expansion or evaporation does not proceed quickly enough (naturally, at  $\mathcal{E} < 1$  ev). The theoretical limit can be reached more easily in a pulsed resonance reactor.

With thermal-neutron reactors the theoretical limit can be closely approached not only in a pulsed reactor but also in a homogeneous reactor. The required velocities of relative motion of the core and the reactor body come close to  $10^2$  m/sec (at  $10^2$  color the core and the reactor body come close to  $10^2$  m/sec (at  $10^2$  color the coolant such velocities are less feasible than for homogeneous reactors as the fuel elements must withstand the coolant flow but their thickness must be reduced to the minimum to avoid excessive internal overheating further increase of the velocity (U > 2VD  $20^2$ ) will be of no avail unless opposing streams of the coolant are used. In a cyclopile this complication of design is very important. So, inside the reactor with a non-ionized coolant the neutron density of order  $10^{14}$ cm<sup>-3</sup> can be obtained only in case the neutron spectrum is thermal.

Strictly speaking with  $\gamma$  /4q  $\sim$  1 formula (39) cannot be applied.

However in the reflector a higher neutron density than 10 14 cm -3 is avilable by forcing the resonant reactor.

 $\chi = 1$ , when U is measured by kilo-With resonant spectrum meters in second. Therefore resonant neutron carryover is not important, the length of the core of a resonant reactor is independent on U and thermal stress is limited only by a permissible velocity of the fuel and the core motion. The neutron density in the reflector, static to the core, does not directly depend on fuel concentration in the core, i.e. hardness of spectrum. This density may be 1-2 orders more the neutron density in the core of the resonant reactor and the limit established by formula (4) is not valid for it.

But one cannot count on a high gain compared to the thermal reactor. In the reflector heat is liberated which is to be removed.

Se thermal neutron carryover by a coelant is also limiting the available flux.

For many purposes, merely obtaining high neutron density is not enough: this density must be retained for a comparatively long peried of time. Obviously, in this respect the cyclopile or homogeneous reactor are superior to the pulsed reactors. It also quite clear that production of a high neutron flux to be maintained for long periods of time with minimum expenditures places specific requirements on the selection of the core materials, its size and construction.

# 7. Appendix

Assume that  $\mathbf{v}_c$  and  $\mathbf{v}_c'$  are the neutron velocities in the centre-of-mass system before and after collision with a nucleus whose velocity and mass number in a laboratory coordinate system are u and A, respectively. As  $V_c = V_c^{\dagger}$  it can be assumed that  $V_c^{\dagger}$ results from the effect produced on V by some random turn operator i.e.

$$\tilde{\mathbf{v}}_{\mathbf{c}}^{*} = \boldsymbol{\theta} \; \tilde{\mathbf{v}}_{\mathbf{c}} \tag{1}$$

 $\widetilde{v}_c^* = \theta \ \widetilde{v}_c$  The average cosine of the turn angle is  $\mathcal M$  , i.e.

$$(\bar{\mathbf{V}}_{c} \, \boldsymbol{\theta} \, \bar{\mathbf{V}}_{c})_{av.} = /M \, \bar{\mathbf{V}}_{c}^{2} \tag{2}$$

As the average value of the vector  $\theta$   $\bar{\mathbf{v}}_{\mathbf{c}}$  is the vector parallel to  $\mathbf{v}_{\mathbf{c}}$ , from (2) it follows

$$(\partial V_c)_{av.} = MV_c$$
 (3)

Take notice,  $\theta$  is a linear operator.

The neutron velocities in the laboratory system before and after collision ( $\bar{V}$  and  $\bar{V}'$ ) are related as follows

$$\overline{V}' = \frac{\overline{V} + A \overline{U}}{I + A} + \Theta \frac{A(\overline{V} - \overline{U})}{I + A} = \frac{I + A \Theta}{I + A} \overline{V} + \frac{A(I - \Theta)}{I + A} \overline{U}$$
(4)

If there are two kinds of nuclei and the probabilities of collision with them are equal to  $P_1$  and  $P_2$  then

$$\bar{V}' = L\bar{V} + \bar{O} \tag{5}$$

where L and O with probabilities P, are respectively equal to

$$\mathcal{L}_{i} = \frac{1 + \mathcal{H}_{i} \, \theta \, i}{1 + \mathcal{H}_{i}} \tag{6}$$

$$\bar{O}\dot{v} = \frac{A_i \left(1 - O_i\right)}{1 + A_i} \bar{U}\dot{v}$$
 (7)

From the formula (3) it follows that by averaging (5) with respect to collision the operator  $\theta_i$  can be substituted with  $m_i$  is that

$$\bar{\mathbf{V}}_{\mathbf{a}\mathbf{v}}^{\bullet} = \mathbf{L}_{\mathbf{a}\mathbf{v}}\bar{\mathbf{V}} + \bar{\mathbf{0}}_{\mathbf{a}\mathbf{v}} \tag{8}$$

where

$$\mathbf{L}_{av} = \mathbf{P}_1 \mathbf{L}_{1av} + \mathbf{P}_2 \mathbf{L}_{2av}, \quad \bar{\mathbf{0}}_{av} = \mathbf{P}_1 \bar{\mathbf{0}}_{1av} + \mathbf{P}_2 \bar{\mathbf{0}}_{2av}$$

and  $L_{i \text{ av}}$  and  $O_{i \text{ av}}$  are obtained from (6) and (7) by substituting  $O_{i}$  with  $M_{i}$ , i.e.

$$\mathbf{L_{av}} = \rho_{i} \frac{1 + A_{i} M_{i}}{1 + A_{i}} + \rho_{2} \frac{1 + A_{2} M_{z}}{1 + A_{2}} = 1 - \left[ \rho_{i} \frac{A_{i} (1 - M_{z})}{1 + A_{i}} + \rho_{2} \frac{A_{z} (1 - M_{z})}{1 + A_{z}} \right]$$
(9)

$$\bar{O}_{av} = P_1 \frac{A_1(1-M_1)}{1+A_1} \bar{U}_1 + P_2 \frac{A_2(1-M_2)}{1+A_2} \bar{U}_2$$
 (10)

Now, let us take a neutron with a randomly oriented velocity  $\overline{V}_o$  after K collisions. Its velocity  $V_k$  can be obtained by applying K

times the formula (5). The average value  $V_k$  av is obtained by subsequent averaging for all collisions and averaging for initial direction  $V_{\bullet}$ . However, since the collisions are statistically independent (we take that  $P_i$  and  $m_i$  are independent on energy) the same result can be reached by applying K times the formula (8), assuming that  $\tilde{V}_{\bullet}$  av = 0. We obtain:

0'L:  

$$\overline{Vav} = \left[1 - \left(P, \frac{1+M.H.}{1+A.} + P_2 \frac{1+M_2A_2}{1+A_2}\right)^{12}\right] \frac{P_1 \frac{A_1}{1+A_1} \left(1-M.\right) \hat{U}_1 + P_2 \frac{A_2}{1+A_2} \left(1-M_2\right) \hat{U}_2}{P_1 \frac{A_1}{1+A_1} \left(1-M.\right) + P_2 \frac{A_2}{1+A_2} \left(1-M_2\right)}$$
